The development of rheumatoid arthritis (RA) is characterized by the generation of a number of pro-inflammatory cytokines and the failure of the immune system to eradicate self-antigens. In the presence of dysregulated T-cell responses and the release of pro-inflammatory cytokines, the pathogenesis of RA is established and remains perpetuated by a number of different mechanisms. After the introduction of the TNF-alpha inhibitor, infliximab, there was a significant improvement in clinical outcomes in RA. The main question was whether the infliximab therapy should be interrupted or continued. The studies of drug interruption in RA are the most important studies, as they are the only way to answer the main question: when to continue or stop the infliximab therapy. The decision to continue or to stop infliximab therapy in RA is more complex than in other rheumatic diseases. Factors affecting the decision are the longer-term outcome, patient preferences, and how rheumatologists evaluate the risk/benefit ratio. Studies designed to answer these questions are needed, and new drugs or different treatment strategies may be an alternative to treat RA.
